Abstract

This paper presents the Gretl function package DPB for estimating dynamic binary models with panel data. The package contains routines for the estimation of the random-effects dynamic probit model proposed by Heckman (1981b) and its generalisation by Hyslop (1999) and Keane and Sauer (2009) to accommodate AR(1) disturbances. The fixed-effects estimator by Bartolucci and Nigro (2010) is also implemented. DPB is available on the Gretl function packages archive.

Keywords: Gretl function package, Random-Effects Dynamic Probit model, Quadratic Exponential model, Gauss-Hermite quadrature, simulated Maximum Likelihood, Conditional Maximum Likelihood.

JEL codes: C23, C25, C63
1 Introduction

Non-linear dynamic models for binary dependent variables with longitudinal data are nowadays quite common in microeconometric applications, especially given the increasing availability of panel datasets. One of the most attractive features of models of the type

\[ y_{it}^* = \gamma y_{i,t-1} + x_{it}' \beta + \alpha_i + \varepsilon_{it} \]

\[ y_{it} = 1\{y_{it}^* \geq 0\} \quad \text{for} \quad i = 1, \ldots, n \quad t = 2, \ldots, T \]

is that they lend themselves very naturally to an interpretation in terms of true state dependence, that is a situation in which the realisation of an event affects the probability of the same event occurring in the future, as opposed to simple time persistence in \( y_{it}^* \), which may be due to covariates \( x_{it} \) and/or to the time-invariant unobserved heterogeneity (Heckman, 1981a).

This feature is particularly attractive when the problem at hand displays some form of path dependence. Therefore, these models have been found to be extremely useful in the analysis of several microeconomic topics: labour force participation, more specifically female labour supply (Heckman and Borjas, 1980; Hyslop, 1999; Carrasco, 2001; Arulampalam, 2002; Stewart, 2007; Keane and Sauer, 2009), self-assessed health condition (Contoyannis et al., 2004; Heiss, 2011; Halliday, 2008; Carro and Traferri, 2012), poverty transitions (Cappellari and Jenkins, 2004; Biewen, 2009), unionisation of workers (Stewart, 2006), welfare participation (Wunder and Riphahn, 2014), remittance decisions by migrants (Bettin and Lucchetti, 2012), and access to credit (Alessie et al., 2004; Brown et al., 2012; Giarda, 2013; Pigini et al., 2014).

While static models are relatively mainstream and are supported by most statistical and econometric software, dynamic models are more complex to implement and, therefore, estimation routines are not always readily available to the practitioner. Compared to their static counterparts, dealing with unobserved heterogeneity in these models raises several complex issues, both statistical and computational in nature. The main statistical problem lies in the so-called “initial conditions problem”: clearly, the recursive nature of the model calls for some kind of conditioning when writing the log-likelihood. This, however, is made problematic by the existence of the time-invariant unobserved individual effects \( \alpha_i \), which is correlated with the initial observation.

Random-Effects (RE henceforth) approaches tackle the initial conditions problem by modelling the joint distribution of the outcomes conditional on \( y_{i1} \). Historically, the first proposal is due to Heckman (1981b) who, building on the static RE estimator, proposed a model for the joint distribution for the response variable \( y_i = [y_{i1}, \ldots, y_{iT}] \), in which a separate reduced-form model for the initial observation \( y_{i1} \) is approximated via a linearised index function. Under suitable distributional assumptions, the joint log-likelihood for \( y_i \) may be evaluated by means of Gauss–Hermite quadrature (Butler and Moffitt, 1982) and estimation may be carried out by Maximum Likelihood (ML).

Generalisations of Heckman’s estimator were later proposed by Hyslop (1999), who introduced autoregressive error terms, and Keane and Sauer (2009), who further generalised it to a model with a more flexible treatment of the initial condition equation. In these cases, however, it is necessary to evaluate multivariate normal integrals with an arbitrary correlation structure among error terms and unobserved heterogeneity. This calls for simulation techniques such as GHK (Geweke, 1989; Hajivassiliou and McFadden, 1998; Keane, 1994), which make estimation considerably more costly in terms of CPU requirements.

Alternatively, Wooldridge (2005) proposed modelling the distribution of individual un-
observed effect $a_i$ conditional on $y_1$ and on the history of covariates instead of dealing with the joint distribution of all outcomes. Wooldridge’s estimator employs techniques for dealing with the initial observation problem in such a way that estimation can be carried out through ordinary RE probit routines with the addition of some ad-hoc explanatory variables. This alternative has become extremely popular, but unfortunately does not lend itself to a natural generalisation to the case with autocorrelated disturbances, which is often called for in practice.

The initial conditions problem can also be circumvented via a Fixed-Effects (FE) approach, which makes it possible to estimate the regression parameters consistently without having to make distributional assumptions on the unobserved heterogeneity. The key idea is to condition the joint distribution of $y_i$ on a suitably defined sufficient statistic for $a_i$. For static logit models, it is possible to define a Conditional Maximum Likelihood (CML) estimator. Its dynamic extension, however, has not gained widespread adoption in empirical work since it cannot be easily generalised to every time-configuration of the panel and requires strong restrictions to the model specification. Moreover, these models generally require that at least a transition between the states 0 and 1 is observed for the individual to contribute to the likelihood. As a result, the number of usable observations often reduces drastically compared to the sample size, especially in the cases when strong persistence in the dependent variable is exactly the reason why a dynamic model is needed.

The first proposal of a FE logit model can be found in Chamberlain (1985): estimation relies on conditional inference and, therefore, is rather simple to perform. Exogenous covariates, however, cannot be included and the proposed sufficient statistic for incidental parameters needs to be determined on a case-wise basis according to the time-series length. Honoré and Kyriazidou (2000) extended Chamberlain’s formulation in order to include explanatory variables; this approach, however, implies the usage of semi-parametric techniques that require a substantial computational effort. Moreover, time-dummies (a customary addition to practically all empirical models) cannot be handled either. Recently, Bartolucci and Nigro (2010) defined a dynamic model, which belongs to the quadratic exponential family and resembles closely a dynamic logit model, which overcomes most of the difficulties encountered by Honoré and Kyriazidou’s estimator and can be implemented by suitably adapting ordinary static FE logit software.

In this work, we present the Gretl implementation of the available set of tools to estimate dynamic models for binary dependent variables in panel datasets by both FE and RE approaches, collected in the DPB (Dynamic Panel Binary) function package. The RE models contained in DPB are the dynamic probit with linearised index initial condition proposed in Heckman (1981b) and the generalisations by Hyslop (1999) and Keane and Sauer (2009). Compared to the other available estimators based on a RE approach, Heckman’s estimator has been shown to suffer from remarkably little small-sample bias (Miranda, 2007; Akay, 2012) and is widely used in microeconomic applications. On the contrary, the estimator proposed by Wooldridge (2005) is not included in the package per se, despite its common use by practitioners, since Gretl already provides suitable functions natively: therefore, we just provide an example showing how to implement it via a simple script. Finally, DPB also contains the software for estimating the quadratic exponential model in Bartolucci and Nigro (2010).

---

1 Similar approaches have been proposed by Orme (1997, 2001) and Arulampalam and Stewart (2009) which we refer to for a more detailed discussion.

2 Estimators based on the FE approach for long panels ($T \to \infty$) have also been proposed, among which Hahn and Newey (2004), Carro (2007), Fernández-Val (2009) Hahn and Kuersteiner (2011), Bartolucci et al. (2014). Here we focus only on short panels ($n \to \infty$), which are the datasets usually available to applied microeconomists.
The rest of the paper is organised as follows: Section 2 first lays the methodological background for the estimators provided in the package, while in Section 3 we discuss the main computational issues of their implementation; Section 4 describes in detail the features of DPBi; Section 5 provides an empirical application based on a dataset of unionised workers extracted from the U.S. National Longitudinal Survey of Youth; Section 6 concludes.

2 Methodological background

A general model for the conditional probability of a binary response variable \( y_{it} \) can be written as

\[
p(y_{it}|\mathcal{F}_t, \alpha_i; \psi_0) \quad \text{for} \quad i = 1, \ldots, n \quad t = 1, \ldots, T,
\]

where \( \mathcal{F}_t \) is the information set at time \( t \) available to individual \( i \), which, in general, may consist of a set of individual covariates \( X_i = [x_{i1}, \ldots, x_{it}] \) as well as the lag of the response variable \( y_{it-1} = [y_{i1}, \ldots, y_{it-1}] \). \( \alpha_i \) is the individual time-invariant unobserved effect, which is assumed to be a continuous r. v.; \( \psi_0 \) is the vector of model parameters. In the simple case where the relevant conditioning information set is \( X_i \), i. e. \( y_{it} \) does not depend on \( y_{it-1} \), the joint probability of \( y_i = [y_{i1}, \ldots, y_{iT}] \) for individual \( i \)

\[
p (y_i | X_i, \alpha_i; \psi_0) = \int_{\mathbb{R}} \prod_{t=1}^{T} p (y_{it} | X_i, \alpha_i; \psi_0) \, dF(\alpha_i).
\]

In a dynamic model \( y_{it} \) is allowed to depend on its past history. When unobserved effects are present, the process for the response variable needs to be initialised in order to account for how \( y_i \) relates to the process before the observations started being available. The dependence on the past of \( y_{it} \) is usually likely to be limited to its first lag, so that the relevant subset of \( \mathcal{F}_t \) is \( [y_{it-1}, X_i] \). Therefore, the joint probability of \( y_i \), conditional on \( X_i \) and \( \alpha_i \), becomes

\[
p (y_i | X_i, \alpha_i; \psi_0) = \int_{\mathbb{R}} p(y_{it} | X_i, \alpha_i; \psi_0) \prod_{t=2}^{T} p (y_{it} | y_{it-1}, X_i, \alpha_i; \psi_0) \, dF(\alpha_i).
\]

The rest of the section describes the RE approach proposed by Heckman (1981b) and its generalisations and the FE approach put forward by Bartolucci and Nigro (2010). In the first case, a reduced form equation for \( p(y_{it} | X_i, \alpha_i; \psi_0) \) is specified. In the second case, the unobserved effect \( \alpha_i \) is eliminated by conditioning \( p (y_i | X_i, \alpha_i; \psi_0) \) on a suitable sufficient statistic and, as a result, the initial condition does not need to be dealt with, so that the joint probability can be written as \( p (y_i | X_i, y_{it-1}, \alpha_i; \psi_0) \).

2.1 Random-Effects approach

The estimator proposed by Heckman (1981b) is based on a standard formulation of a dynamic RE binary choice model with an additional equation for the initial observation \( y_{i1} \):

\[
y_{it} = 1\{ y_{it-1} + x'_{it} \beta + \alpha_i + \epsilon_{it} \geq 0 \} \quad \text{for} \quad i = 1, \ldots, n \quad t = 2, \ldots, T \quad (1)
y_{i1} = 1\{ x'_{i1} \pi + \theta \alpha_i + \epsilon_{i1} \geq 0 \} \quad \text{for} \quad i = 1, \ldots, n \quad (2)
\]
where \( y_{it} \) is the binary response variable, \( 1 \{ \cdot \} \) is an indicator function, \( x_{it} \) is a vector of individual covariates and \( z_{i1} \) contains the values of \( X_i \) in the first period and pre-sample information that can be used as exclusion restrictions. The assumptions on \( \alpha_i \) and \( \varepsilon_i \) are: \( E[\varepsilon_{it} | X_i, \alpha_i] = 0 \); orthogonality of \( \alpha_i \) and \( X_i \), \( E[\alpha_i | X_i] = 0 \); joint normality conditional on \( X_i \), \( \left[ \theta \alpha_i + \varepsilon_{i1}, \alpha_i + \varepsilon_{i2}, \ldots, \alpha_i + \varepsilon_{iT} \right]' \sim N(0; \Sigma) \) with

\[
\Sigma = \begin{bmatrix}
1 + \theta^2 \sigma^2 \alpha_i & \theta \sigma^2 \alpha_i & \theta \sigma^2 \alpha_i & \ldots \\
\theta \sigma^2 \alpha_i & 1 + \sigma^2 \alpha_i & \sigma^2 \alpha_i & \ldots \\
\theta \sigma^2 \alpha_i & \sigma^2 \alpha_i & 1 + \sigma^2 \alpha_i & \ldots \\
\vdots & \vdots & \vdots & \ddots
\end{bmatrix}
\]  

where \( \sigma^2 \alpha_i = V(\alpha_i) \).

In this paper, this model will be referred to as the “DP” model (Dynamic Probit). Note that the distributional assumption implies independence between \( \alpha_i \) and \( \varepsilon_i \) and absence of autocorrelation in \( \varepsilon_i \), i.e. \( E[\varepsilon_{it} \varepsilon_{is}] = 0 \) for \( t, s = 1, \ldots, T \) and \( t \neq s \). Under these assumptions, the parameter vector \( \psi = [\beta' , \gamma, \pi', \theta, \sigma_\alpha] \) can be estimated by ML, and the \( i \)-th contribution to the likelihood is given by the following expression:

\[
\mathcal{L}_i(\psi) = \int_{\mathbb{R}} \Phi \left[ (z'_{i1} \pi + \theta \alpha_i)(2y_{i1} - 1) \right] \prod_{t=2}^{T} \Phi \left[ (\gamma y_{it-1} + x'_{it} \beta + \alpha_i)(2y_{it} - 1) \right] d\Phi \left( \frac{\varepsilon_{it}}{\sigma_\alpha} \right),
\]

where \( \Phi(\cdot) \) is the standard normal c.d.f. Since the unobserved effects are normally distributed, the integral over \( \alpha_i \) can be evaluated by means of Gauss-Hermite quadrature (Butler and Moffitt, 1982).

Hyslop (1999) considered an interesting generalisation of Heckman’s approach by allowing for autocorrelation in \( \varepsilon_i \). In terms of interpretation, this setting makes it possible to further disentangle two different sources of time persistence: in Heckman (1981b), the true state dependence captured by \( \gamma \) in (1) is isolated form the persistence induced by time-invariant unobserved effects \( \alpha_i \); with autocorrelated errors, the persistence in the time-varying unobserved effects is also parametrised. The error terms \( \varepsilon_{it} \) follow the AR(1) process

\[ \varepsilon_{it} = \rho \varepsilon_{it-1} + \eta_{it} \quad \text{for} \quad t = 2, \ldots, T \]

where \(|\rho| \leq 1\) and \( \eta_{it} \sim N(0, 1 - \rho^2) \). Therefore, the variance-covariance matrix of the error components needs to be modified as follows:

\[
\Sigma = \begin{bmatrix}
1 + \theta^2 \sigma^2 \alpha_i & \rho + \theta \sigma^2 \alpha_i & \rho^2 + \theta \sigma^2 \alpha_i & \ldots \\
\rho + \theta \sigma^2 \alpha_i & 1 + \sigma^2 \alpha_i & \rho + \sigma^2 \alpha_i & \ldots \\
\rho^2 + \theta \sigma^2 \alpha_i & \rho + \sigma^2 \alpha_i & 1 + \sigma^2 \alpha_i & \ldots \\
\vdots & \vdots & \vdots & \ddots
\end{bmatrix}
\]  

Note that (4) reduces to (3) for \( \rho = 0 \); hence, we will call this the “ADP” model (ARI Dynamic Probit).

Recently, Keane and Sauer (2009) introduced a more general version of \( \Sigma \) in which an additional parameter is defined. The starting point is to modify (2) as

\[ y_{it} = 1 \{ z'_{i1} \pi + \theta \alpha_i + u_i \geq 0 \}, \]

with \( E(u_i, \varepsilon_{i2}) = \tau \). Note that since both \( u_i \) and \( \varepsilon_{it} \) need to be normalised for identification, \( \tau \) is effectively a correlation coefficient, so \(|\tau| \leq 1\) holds by the Cauchy-Schwartz inequality.
Therefore, (4) becomes:
\[
[\theta a_t + u_t, a_i + \varepsilon_{YT}, \ldots, a_i + \varepsilon_{IT}]' \sim N(0, \Sigma) \text{ with }
\]
\[
\Sigma = \begin{bmatrix}
1 + \theta^2 \sigma_a^2 & \tau \rho + \theta \sigma_a^2 & \tau \rho^2 + \theta \sigma_a^2 & \ldots \\
\tau \rho + \theta \sigma_a^2 & 1 + \sigma_a^2 & \rho + \sigma_a^2 & \ldots \\
\tau \rho^2 + \theta \sigma_a^2 & \rho + \sigma_a^2 & 1 + \sigma_a^2 & \ldots \\
\vdots & \vdots & \vdots & \ddots
\end{bmatrix}
\] (5)

Notice that (5) is equal to (4) for \( \tau = 1 \) and equal to (3) for \( \rho = 0 \). The acronym we will use henceforth for this model is “GADP” (Generalised ADP).

In theory, its greater generality makes model (5) more appealing for applied work than its restricted counterpart (4) and, a fortiori, (3). However, there are two factors that may make it advisable to opt for the more restrictive versions of the model. The first one is computational complexity: the specification of \( \varepsilon_{it} \) as an AR(1) process makes it impossible to evaluate the joint probability \( p(\cdot) \) by integrating out the random effect \( a_i \). Instead, \( T \)-variate normal probabilities must be evaluated by simulation by using the GHK algorithm (Geweke, 1989; Hajivassiliou and McFadden, 1998; Keane, 1994) in order to compute the likelihood function:
\[
\mathcal{L}_r(\psi) = \frac{1}{R} \sum_{r=1}^{R} \Phi_{Tr}(a_r, b_r, C)
\]
with \( a_i = (z'_{it} \pi)(2y_{it} - 1) \) and \( b_i = [b_{it_2}, \ldots, b_{iT}] \), where \( b_{it} = (\gamma y_{it-1} + x'_{it} \beta)(2y_{it} - 1); C \) is the lower-triangular Cholesky factor of \( \Sigma \) defined in (4) or (5), and \( r \) is the number of random draws used in the simulation. The second one is that, in finite samples, the ADP and GADP models (especially the latter) may suffer from serious identification problems for certain regions of the parameter space; in some cases, this could cause serious numerical problems for conducting inference, because of insufficient curvature of the log-likelihood function. These issues will be described in greater detail in section 3.4.

2.2 Fixed-Effects approach

With the exception of linear probability models, FE approaches to the estimation of dynamic binary choice models are usually based on the dynamic logit formulation. In this case, model (1) is subject to strict exogeneity conditional on \( a_i \) and it is assumed that the error terms \( \varepsilon_{it} \), \( t = 1, \ldots, T \), are i.i.d. standard logistic random variables. Therefore, the probability of observing \( y_{it} \) can be written as
\[
p(y_{it}|y_{it-1}, x_{it}, a_i; \psi) = \frac{\exp \left[ y_{it} \left( \gamma y_{it-1} + x'_{it} \beta + a_i \right) \right]}{1 + \exp \left[ \gamma y_{it-1} + x'_{it} \beta + a_i \right]}.
\]

As is well known (Chamberlain, 1985), in the static case (\( \gamma = 0 \)) the total score \( y_{it} \equiv \sum_y y_{it} \) is a sufficient statistic for \( a_i \), on which the distribution of \( y_i \) can be conditioned, so as to remove the unobserved individual effect \( a_i \); unfortunately, in the dynamic logit model (\( \gamma \neq 0 \)) equivalent sufficient statistics may exist, but they must be derived on a case-wise basis. Moreover, the inclusion of explanatory variables requires restrictions on their distribution and a non-negligible computational effort (Honoré and Kyriazidou, 2000).

The joint probability of observing the response configuration \( y_i \) conditional on the initial observation \( y_{i1} \) is
\[
p(y_i|X_i, y_{i1}, a_i; \psi) = \frac{\exp \left[ \sum_y y_{it} y_{it-1} \gamma + \sum_y y_{it} x'_{it} \beta + y_{i1} a_i \right]}{\prod_y \left[ 1 + \exp \left( \gamma y_{it-1} + x'_{it} \beta + a_i \right) \right]} \]
(6)
where sums and products go from \( t = 2 \) to \( T \).

The quadratic exponential model proposed by Bartolucci and Nigro (2010) (for which we will use, from here onward, the “QE” acronym) directly defines the joint probability of \( y_i \) as

\[
p(y_i | X_i, y_{i1}, \alpha_i; \psi) = \frac{\exp \left( \sum_{t} y_{it} y_{it-1} \gamma + \sum_{t} y_{it} x_{it}' \beta_1 + y_{it} (\mu + x_{it}' \beta_2) + y_{i+} \alpha_i \right)}{\sum_{b \in B} \exp \left( \sum_{t} b_t b_{t-1} \gamma + \sum_{t} b_t x_{it}' \beta_1 + b_T (\mu + x_{iT}' \beta_2) + b_{+} \alpha_i \right)}
\]

where \( b_+ \equiv \sum_t b_t \) and \( B \equiv \{ b : b \in \{0,1\}^T \} \), that is the set of all possible \( T \)-vectors \( b \) containing zeros and ones.

This probability closely resembles the one in (6) and, under (6) and (7), Bartolucci and Nigro (2010) show that \( \gamma \) has the same interpretation in terms of log-odds ratio between each pair of consecutive \( y_{it} \)s. It can be shown that the total score \( y_{i+} \) is a sufficient statistic for the unobserved effects \( \alpha_i \) in (7). The conditional distribution based on the total score is

\[
p(y_i | X_i, y_{i1}, y_{i+}; \psi) = \frac{p(y_i | X_i, y_{i1}, \alpha_i; \psi)}{p(y_{i+} | X_i, y_{i1}, \alpha_i; \psi)} = \frac{\exp \left[ \sum_{t} y_{it-1} y_{it} \gamma + \sum_{t} y_{it} x_{it}' \beta_1 + y_{it} (\mu + x_{it}' \beta_2) \right]}{\sum_{b, b_+ = y_{i+}} \exp \left[ \sum_{t} b_t b_{t-1} \gamma + \sum_{t} b_t x_{it}' \beta_1 + b_T (\mu + x_{iT}' \beta_2) \right]}
\]

So that the denominator contains only those vectors \( b \in B \) such that \( b_+ = y_{i+} \). By using the above conditional probability, the conditional log-likelihood can be written as

\[
\ell(\psi) = \sum_{i=1}^{n} 1\{0 < y_{i+} < T\} \log p(y_i | X_i, y_{i1}, y_{i+}; \psi)
\]

and maximised with respect to \( \psi = [\gamma, \beta_1', \mu, \beta_2']' \). We refer the reader to Bartolucci and Nigro (2010) for details on the score and Hessian of \( \ell(\psi) \).

3 Computation and numerical issues

3.1 Treatment of missing values

The DPB package can handle unbalanced panels, as long as there are enough consecutive observations for each longitudinal unit. If we use \( T_i \) to indicate the maximum time span of consecutive observations for individual \( i \), the requirements for a cross-sectional unit \( i \) to be included in the sample are

- \( T_i \geq 2 \) for the DP, ADP and GADP models;
- \( T_i > y_{i+} > 0 \) for the QE models.

For each unit, the longest available consecutive set of observations per individual is used. If more than one sequence is available, we take the most recent one. Of course, the choices above imply the assumption that observability of \( y_{it} \) and/or \( x_{it} \) is totally independent of the random variables included in the models. For further details, see Albarrán et al. (2015).
3.2 Computation of the log-likelihood and its derivatives

The two most important algorithms employed for computing the log-likelihood of the four models handled by the package are Gauss-Hermite quadrature for the DP model and the GHK algorithm for the ADP and GADP models.\(^3\) As for the QE model, the main problem lies in efficient computation of the denominator in equation (8), which does not include problematic functions, but is made tricky by the multiplicity of cases to consider. Fortunately, a recursive approach is possible, which we will describe in subsection 3.3.

For Gauss-Hermite quadrature, the DPB function package uses the Gretl native function *quadtable*, which guarantees good speed and accuracy. The number of quadrature point can be chosen by the user, with a default of 24. The DPB package does not include, at present, the option of using adaptive quadrature methods as recommended, for example, in Rabe-Hesketh et al. (2002).

As for simulation-based methods, DPB relies on the Gretl function *ghk*, which natively provides analytic derivatives. This function does not implement optimisation techniques such as the pivoting method by Genz (1992), because Genz's method may introduce discontinuities that would make numerical differentiation problematic. On the other hand, it automatically switches to a parallel implementation on a multi-core machine in a shared-memory environment, which gives a noticeable performance boost on modern CPUs.\(^4\) The default method for feeding the uniform sequence to the GHK algorithm is by using Halton sequences, but the user can switch to the uniform generator used by default in Gretl (the SIMD-oriented implementation of the Mersenne Twister algorithm described in Saito and Matsumoto (2008)) if so desired.

The choice method for optimisation is BFGS with analytical derivatives for the probit models DP, ADP and GADP; this has generally proven quite effective and remarkably more robust and efficient than Newton-Raphson. Alternatively, its limited-memory variant described in Byrd et al. (1995) can also be used. Two of the parameters in the covariance matrix $\Sigma$ are in fact maximised via an invertible transformation to help numerical stability: $\sigma_\alpha^2$ is expressed as its natural logarithm and $\rho$ through the (inverse) hyperbolic tangent transform, so that the parameters that enter the actual maximisation routine are unbounded. Initial values for $\beta$, $\gamma$, and $\pi$ are obtained by straightforward linear probability models, while $\sigma_\alpha$ and $\theta$ are both set to 1.

For the QE model, instead, the method of choice is Newton-Raphson, which takes advantage of the fact that the computation of the Hessian matrix is remarkably inexpensive once the analytical score has been been obtained. Initial values for $\gamma$, $\beta_1$, $\mu$ and $\beta_2$ are simply 0.\(^5\)

3.3 Computation of the denominator term in the QE model

The peculiar nature of the QE model makes it impossible to compute its denominator in a manner akin to the algorithm used in several packages for the ordinary conditional logit model, which is in turn a variation of the recursive algorithm by Krailo and Pike (1984).

The algorithm we implement has the virtue of relegating the recursive computation of the relevant combinations ($b$ vectors) at the initialisation stage; by memorising the rele-

---

\(^3\)It is perfectly possible to use the GHK technique for estimating the DP model, but it would be rather inefficient. However, it may be interesting to do so for comparison purposes, so the package makes it possible via an option.

\(^4\)Gretl also provides MPI extensions for distributed-memory architectures, but they have not been used in the DPB package.

\(^5\)This choice, to our surprise, was found to outperform logit-based initialisation.
vant information into an array of matrices, we avoid recursion at each computation of the likelihood. Our algorithm can be briefly described as follows.

The denominator in equation (8) can be easily written as a function of a matrix $Q$, whose size and elements are function of three scalars: $T_i$, $y_{i+}$ and $y_{is}$, where $y_{is} = \sum y_{it} y_{it-1}$ is the number of consecutive ones in $y_i$.

Define an injective index function $j = j(T, y_{i+}, y_{is})$ (where we omit the $i$ subscript for conciseness). Obviously, all individuals in the sample with the same values for $T_i$, $y_{i+}$ and $y_{is}$ can share the same $j$ index. The idea is to pre-generate all the needed $Q_j$ matrices and store them in an array; since $T_i \geq y_{i+} > y_{is}$ holds, the array can have at most $T_{max}^2 (T_{max} - 1)$ elements, although in practice the number of distinct elements in the array will be much smaller. In a typical panel data setting, it is unlikely that more than a few hundred distinct $Q_j$ matrices will have to be computed and stored in memory.

The internal structure of $Q_j$ is

$$Q_j = \left[ Q^1(T, y_{i+}) | q^2(y_{is}) \right]$$

in which

1. $Q^1(T, y_{i+})$ is a matrix with $T! / y_{i+}! (T-y_{i+})!$ rows and $T$ columns whose rows are the elements of $B$ (see Section 2.2)

2. $q^2(y_{is})$ is a column vector holding the number of times in which you get consecutive ones in the corresponding row of $Q^1$.

For example, consider an individual for whom $y_i = [0, 1, 1, 0]$; in this case we have $T_i = 4$, $y_{i+} = 2$ and $y_{is} = 1$. The corresponding $Q$ matrix would be

$$Q = \begin{bmatrix}
1 & 1 & 0 & 0 & 1 \\
1 & 0 & 1 & 0 & 0 \\
0 & 1 & 1 & 0 & 1 \\
1 & 0 & 0 & 1 & 0 \\
0 & 1 & 0 & 1 & 0 \\
0 & 0 & 1 & 1 & 1
\end{bmatrix}$$

which lists all the possibilities. We call the “relevant” row $k_i$ the one which contains the sequence $y_i$ actually observed (the third row of $Q$ in this example, so $k_i = 3$).

The $Q^1(T, y_{i+})$ matrices can be computed recursively by noting that

$$Q^1(T, y_{i+}) = \begin{bmatrix}
Q^1(T-1, y_{i+}) & 0 \\
\vdots & \vdots \\
0 & 1 \\
Q^1(T-1, y_{i+} - 1) & 0 \\
\vdots & \vdots \\
1 & 1
\end{bmatrix}$$
with the special cases

\[
Q^1(n, 0) = [0 \ldots 0] \\
Q^1(n, 1) = I_n \\
Q^1(n, n) = [1 \ldots 1]
\]

Since none of the necessary \( Q_j \) depend on parameters to be estimated, they are precomputed in a preliminary loop and stored in an array of matrices. The algorithm employed can therefore be given the following schematic description:

1. initialise an empty array of matrices \( Q \);
2. for each individual \( i \);
   (a) compute the \( j(i) \) index as a function of \( T_i, y_{i+} \) and \( y_{i*} \);
   (b) if \( Q_j \) has already been computed, stop and go to the next individual \( i \); else
      i. compute \( Q^1(T_i, y_{i+}) \) via the recursive method described above;
      ii. store the relevant row \( k_i \) for individual \( i \).
      iii. compute \( Q_j \) via equation (9);
      iv. store \( Q_j \) into the array at position \( j \).

Once this is done, the likelihood for individual \( i \) in (8) becomes a simple function of \( k_i \) and \( Q_j \), which don’t need to be recomputed during the Newton-Raphson iterations.

### 3.4 Identification of \( \rho \) and \( \tau \) in short panels for RE probit models with AR(1) disturbances

When estimating RE probit models with autocorrelated errors, maximising the log-likelihood may be quite challenging from a numerical point of view because of weak identification in some of the parameters. Consider first the ADP model, in which the covariance matrix of the compound disturbance terms for a unit is given in equation (4). It is quite obvious that some combinations of the parameters give rise to a very badly conditioned matrix. This happens, in particular, when \( \theta \simeq 1 \) and \( \rho = 1 - \epsilon \) (for “small” \( \epsilon \)). In those cases, \( \Sigma \) will be very close to be singular, especially in those units for which the time dimension is short (note that all these three possibilities are far from being uncommon in practice). The typical outcome is BFGS taking many iterations to converge or, worse, not converging at all.

The situation is even worse for the GADP model, whose covariance matrix is given in equation (5): first, since the covariance matrix depends on four parameters, an elementary order condition dictates that only the observations for which \( T_i \geq 3 \) will provide enough curvature to the log-likelihood to separately identify all four parameters, which is not an overly restrictive requirement. However, note that the parameter \( \tau \) only appears in products like \( \tau \cdot \rho^t \), with \( 1 \geq t \geq (T_i - 1) \). This implies that, for obtaining enough curvature in the objective function in the direction of \( \tau \), the sequence \( \rho, \rho^2, \rho^3, \ldots \) must be noticeably different (from a numerical point of view) from a sequence of constants. In practice, this implies that estimation is likely to fail anytime (i) \( \rho \) is very close to 0 or to 1 and (ii) \( T_{\text{max}} \) is small, unless \( N \) is truly enormous. In the limit, if \( \rho = 0 \) or \( \rho = 1 \) the model is under-identified even when \( N \to \infty \) and \( T \to \infty \).
4 The DPB function package

In Gretl, function packages are collections of user defined functions made available to other users. The user can download and install the function packages available on the Gretl server by menu or script. A function package can be downloaded and installed simply by invoking the install command:

Gretl console: type ‘help’ for a list of commands
? install DPB
Installed DPB

Then, in each work session, the function package needs to be loaded by:

? include DPB.gfn

We refer the reader to the Gretl user guide for illustration on how to download and install function packages from the menu. The function package DPB includes four functions that handle model set-up, option management, estimation and printing of results. A summary of these functions is given in Table 1 and a detailed description is contained in the section “List of Public Functions” of the DPB documentation file.

In the rest of this section, we first illustrate how to estimate the RE models DP, ADP and GADP described in Section 2.1, then we show how to perform estimation of the QE model proposed by Bartolucci and Nigro (2010). All the script files and datasets used in this section are available in the folder your path/.gretl/functions/DPB/examples, created after the installation of DPB. The minimum version of Gretl required to use the package is 1.10.0.

4.1 Random-Effects dynamic probit

We start by describing how DPB handles the RE approach proposed by Heckman (1981b), by using an artificial dataset generated following (1) and (3):

\[ y_{it} = 1\{1 + 0.6 y_{it-1} + 0.5 x_{it} + \alpha_i + \epsilon_{it} \geq 0\} \]
\[ y_{i1} = 1\{1 + x_{i1} + z_{i1} + 1.2 \alpha_i + \epsilon_{i1} \geq 0\}, \]
\[ \sigma^2_{\alpha} = 1, \quad \alpha_i \sim N(0, \sigma^2_{\alpha}) \]
\[ x_{it} \sim N(0,1) \quad z_{it} \sim U(0,1), \]
for \( i = 1, \ldots, 4096 \) and \( t = 1, \ldots, 6 \).

We also assume that \( \rho = 0 \), so \( \epsilon_{it} \) is not autocorrelated. For the purpose of replication, we provide the script file RE_gendata.inp: this script generates dynamic binary data under normality with the error structure in (3), sets the parameter values in (10) and stores the artificial data in DP_artdata.gdtb. The following code is provided in the DP_example.inp script file.

Once the DPB function package has been downloaded from the Gretl server, a simple Hansl script to estimate the DP model is:

```
set echo off
set messages off
include DPB.gfn
open DP_artdata.gdtb
```

setobs id time --panel-vars

list X = const x
list Z = const x z

b = DPB_setup("DP", y, X, Z)
DPB_estimate(&b)

The first two lines of code just prevent Gretl from echoing unnecessary output, while the include command loads the function package. After setting the panel structure, which is required for DPB to work, the lists of explanatory variables are created. In the next line, the call to the public function DPB_setup initialises the model and returns a bundle: the first argument is a string containing the name of the model to be estimated ("DP" in this case). The remaining arguments y, X, Z are the dependent variable, the list of explanatory variables for the primary equation and those for initial condition equation.

The function DPB_estimate takes as its argument the pointer to the model bundle and fills the bundle with the estimated quantities. The bundle elements can be listed by simply typing print b. A detailed description of the bundle elements is given in the DPB documentation. Bundle elements can be accessed by the syntax npar = b["npar"] or npar = b.npar. The returned bundle can also be stored as an XML file by using the Gretl built-in function bwrite(b, "mod") and reloaded, if necessary, by the companion function b = bread("mod"). The DPB_estimate function also assigns initial values for the parameters; the user can supply a vector of initial values as a second argument to DPB_estimate. For instance

```
scalar npar = b.npar
inipar = muniform(npar, 1)
DPB_estimate(&b, &inipar)
```

To print out the results, the corresponding public function is called

```
DPB_printout(&b)
```

which produces the following output:

Dynamic Probit model
Dependent variable: y
Units: 4096 (observations: 24576)
Covariance matrix: Sandwich
Method: Gaussian quadrature with 24 quadrature points

Log-likelihood = -10771.971  AIC = 21559.942  BIC = 21624.818  HQC = 21580.958

Wald test = 1325.22 (1 df); p-value = 3.73248e-290

where coefficients, standard errors and related z-tests are reported for the state dependence parameter $\gamma$, the coefficients of the main equation $\beta$, the coefficients of the initial conditions equation $\pi$, and the covariance matrix parameters $\theta$ and $\sigma$. At the end of the output table, a Wald test for the joint significance of the explanatory variables in the main equation is reported.

As shown in the output headings, the model has been estimated using the Gauss-Hermite quadrature with 24 quadrature points, and the variance-covariance matrix of the parameters has been estimated by a sandwich formula. These are the default settings, which can be altered by the user by calling the public function DPB_setoption before DPB_estimate. For instance,

```c
err = DPB_setoption(&b, "nrep", 32)
DPB_estimate(&b)
```

DPB_setoption returns a scalar (called err in the above code lines) containing 0 if the option is valid and successfully set, an error code otherwise. For a detailed description of the available options, see Table 2.

In the example above, the string `nrep` and the scalar 32 are used to set the number of quadrature points to be used during estimation.

The DP model can also be estimated by computing the multivariate normal probabilities by GHK instead of using numerical integration by Gauss-Hermite quadrature. After the call to DPB_setup, the user can switch the method form GHQ (default) to GHK by calling DPB_setoption as follows

```c
err = DPB_setoption(&b, "nrep", 100)
er = DPB_setoption(&b, "method", 1)
```

When the GHK method is invoked, a Halton sequence is used by default. The user may instead use random draws from a uniform distribution by setting "draws" to 1, as described in Table 2. The number of Halton points used by the GHK algorithm has a default value of 128 that can also be modified by the function DPB_setoption with the string `nrep` and the number of points, as illustrated earlier in this section.

In some cases, estimation can be computationally quite intensive. In particular, the GHK algorithm is quite sensitive to the time dimension of the panel, as $T$ sets the dimension for the covariance matrix (3). Table 3 reports the performance of the DPB function package for different numbers of quadrature points and GHK replications to give the user an idea of the trade-off between algorithm quality and time. The table was obtained by the following command lines:

```c
b = DPB_setup("DP",y,X,Z)
er1 = DPB_setoption(&b, "verbose", 2)
er2 = DPB_setoption(&b, "vcv", 1)
```
Table 2: Description of `DPB_setoption`'s arguments

  DPB_estimate(&b)
  DPB_printout(&b)
  t_$i = $stopwatch
  print t_$i
endloop
```

The above commands are stored in the sample script `DP_perf.inp`. The `verbose` string and the scalar 2 in `DPB_setoption` result in the printing of the values of parameters and gradients at each iteration in the log-likelihood maximisation. In addition, we use the option `vcv` with value 1 to set the covariance matrix estimator to OPG, which is the least computationally demanding. Since the `method` option was left unmodified, the above code estimates the dynamic probit by GHQ, with 16, 24, and 32 quadrature points. If, instead, one wishes to inspect the performance of the GHK algorithm, the method must be changed via `err = DPB_setoption(&b, "method", 1)` after the set-up function; in Table 3 we display the results obtained by setting the number of to 128, 192, and 256. The estimates obtained via GHQ do no exhibit remarkable differences from each other. Conversely, the GHK algo-

Results obtained on a system with two Intel(R) Pentium(R) CPU G640 @ 2.80GHz processors.

The algorithm obviously takes a longer time to yield the results because of its nature. In particular, the cpu-time increases in a roughly linear way with the number of replications.

As described in Section 2.1, the ADP and GADP models can be formulated by setting the variance-covariance matrix of the error terms as in (4) and (5) respectively. Such structure does not allow the use of GHQ to evaluate the relevant normal integral and GHK has to be used instead. In order to illustrate how DPB handles these extensions, we use the simulated dataset in (10) with \( \rho = 0.3, \tau = 1 \) (stored in ADP_artdata.gdtb) and \( \rho = 0.3, \tau = 0.6 \) (stored in GADP_artdata.gdtb) to build (4) and (5), respectively. The ADP model can be estimated by setting the the first argument of DPB_setup to "ADP":

```plaintext
open ADP_artdata.gdtb
list X = const x
list Z = const x z
b = DPB_setup("ADP",y,X,Z)
DPB_estimate(&b)
DPB_printout(&b)
```

The above code is also stored in the script file ADP_example.inp. In this case, if the user tries to set GHQ as estimation method, a warning message is printed and the estimation proceeds with GHK using 128 Halton points. The above code also returns the following output:

```
AR(1) Dynamic Probit model
Dependent variable: y
Units: 4096 (observations: 24576)
Covariance matrix: Sandwich
Method: GHK with 128 Halton points

<table>
<thead>
<tr>
<th>coefficient</th>
<th>std. error</th>
<th>z</th>
<th>p-value</th>
</tr>
</thead>
<tbody>
<tr>
<td>y(-1)</td>
<td>0.604903</td>
<td>0.0811089</td>
<td>7.458</td>
</tr>
</tbody>
</table>
```
Similarly, the GADP model can be estimated by setting the first value in the DPB_setup to “GADP” (the code is provided in GADP_example.inp):

```plaintext
open GADP_artdata.gdtb
list X = const x
list Z = const x z
b = DPB_setup("GADP",y,X,Z)
```

After loading data with $\rho = 0.3$ and $\tau = 0.6$, running the estimation functions produces:

```
Generalised AR(1) Dynamic Probit model
Dependent variable: y
Units: 4096 (observations: 24576)
Covariance matrix: Sandwich
Method: GHK with 128 Halton points
```

4.2 Quadratic Exponential model

We exemplify the FE estimator proposed in Bartolucci and Nigro (2010), by means of artificial data set, generated in a similar way as in (10):

\[
y_{it} = 1 \{0.6 y_{it-1} + 0.5 x_{1it} + 0.5 x_{2it} + \alpha_i + \epsilon_{it} \geq 0\}
\]

\[
y_{1i} = 1 \{0.5 x_{1i1} + 0.5 x_{2i1} \alpha_i + \epsilon_{1i} \geq 0\} \quad \text{for } i = 1, \ldots, 1024 \quad t = 1, \ldots, 6
\]

where \(\alpha_i\) is generated as in (10), the regressors \(x_{1it}\) and \(x_{2it}\) are standard normal random variables and the error terms \(\epsilon_{it}\) are logistically distributed with zero mean and variance \(\pi^2/3\). The file QE.gendata.inp contains the Hansl code for generating the artificial data also stored in QE.artdata.gdtb. A simple script to estimate the quadratic exponential model described in 2.2 is:

```plaintext
set echo off
set messages off
include DPB.gfn
open QE_artdata.gdtb
setobs id time --panel-vars
list X = x1 x2 x3
b = DPB_setup("QE",y,X)
DPB_setoption(&b, "vcv", 2)
DPB_estimate(&b)
DPB_printout(&b)
```

The above commands are also stored in QE_example.inp. After the required panel structure is set and the list of explanatory variables has been created, the script calls the set-up function with the string "QE" as its first argument. For illustrative purposes, in the above example the covariance matrix estimator is set to the Hessian by setting the vcv option to 2. The script returns the following output:

Quadratic Exponential model
Dependent variable: y
Units: 821 (observations: 4105)
Total units: 1024 (total observations: 5120)
Covariance matrix: Hessian

Notice that, since only the units with $0 < y_{i+} < T$, DPB reports in the output headings the number of actual contributions to the log-likelihood. The output reports coefficients, standard errors and $z$-statistics for the parameters in (8): the coefficient associated with the lagged dependent variable $\gamma$, the parameters $\beta_i$ for the explanatory variables and, finally, the parameters associated with the last observation, $[\mu, \beta_2']$.

The handling of time dummies in the model specification deserves a special mention. For instance, let us discuss the case of a balanced dataset: in a panel of $T$ periods, the QE model identifies $T - 3$ time effects, as two dummies are dropped for the initial and rank condition in the main equation; another one gets dropped as the observation at time $T$ is handled separately in the model specification (see expression (8)) and it includes an intercept term. An example is given in the script file QE_example.inp.

## 5 Examples: the union dataset

In this section, we illustrate the DPB function package by means of two empirical applications. In the first exercise, we replicate the example proposed by Stewart (2006), used to present the software components to estimate RE dynamic probit models in Stata.

In the second, we show how to implement in Hansl the estimator proposed by Wooldridge (2005), how to compute Partial Effects, and compare it with the DP model available in DPB. As a side-product, we show how to implement the popular Correlated Random Effects (CRE) approaches (Mundlak, 1978; Chamberlain, 1980) in Gretl and within the DPB function package.

Both examples use data extracted from the U.S. National Longitudinal Survey of Youth on unionised workers, a very popular dataset often used as a benchmark for RE (dynamic) models for binary dependent variables with longitudinal data.

### 5.1 Example 1

In the following, we replicate the empirical example provided in Stewart (2006), where the union dataset is used to illustrate the Stata software component for the estimation of the
RE dynamic probit models of Heckman (1981b), DP, and Hyslop (1999), ADP.  

Differently from DPB, the software provided by Stewart (2006) unsurprisingly does not allow for the implementation of the estimator proposed by Keane and Sauer (2009). The results reported in this section can be replicated using the script file union_example1.inp and the data file union_full.gdtb.

Using the variables given in the union dataset, a model is specified for the binary dependent variable at time $t$ and for the initial condition as in Heckman (1981b):

$$
\begin{align*}
\text{union}_{it} &= \mathbf{1}\{\gamma \text{union}_{it-1} + \beta_0 + \beta_1 \text{age}_{it} + \beta_2 \text{grade}_{it} + \beta_3 \text{south}_{it} + \alpha_i + \epsilon_{it} \geq 0\}\}, \\
\text{union}_{i1} &= \mathbf{1}\{\pi_0 + \pi_1 \text{age}_{i1} + \pi_2 \text{grade}_{i1} + \pi_3 \text{south}_{i1} + \pi_4 \text{not_smsa} + \theta \alpha_i + \epsilon_{i1} \geq 0\}\}
\end{align*}
$$

for $i = 1, \ldots, n$ and $t = 2, \ldots, T$, where union is the binary dependent variable, age is the age at time $t$, grade are the years of schooling and south is a dummy variable for living in the South. For the initial condition, not_smsa, living outside a standard metropolitan statistical area, is used as an exclusion restriction.

The dataset is an unbalanced panel which starts in 1970 and ends in 1988; a few years do not appear in the dataset, so several gaps are present. The number units is 4434 and the maximum time length $T = 12$, for a total of 26200 observations. Simple descriptive statistics on the dataset are given by the summary command, followed by the variable names:

```
? summary union age grade south not_smsa --simple
```

<table>

</tbody>
</table>

In order to replicate the example provided in Stewart (2006), the dataset needs to be sub-sampled: only the years from 1978 are kept and 1983 is dropped; in addition, the panel is balanced by keeping units that are present for six consecutive waves. The following code sub-samples the dataset in order to keep the portion used in Stewart (2006) and stores it, for convenience, in the Gretl data file union.gdtb:

```
# Replicate example provided in Stewart (2006)
series valid = 0
smpl year>78 --restrict
smpl year!=83 --restrict
matrix m = aggregate(const,idcode)
series nwav = replace(idcode, m[,1], m[,2])
smpl nwav==6 --restrict
series valid = 1
store union.gdtb
open union.gdtb --quiet
smpl full
smpl valid --dummy
setobs idcode year --panel-vars
```

The data for this example were retrieved from the URL. As far as we are aware, usage of this dataset was unrestricted for academic use and we believe that a comparison between our results and Stewart’s was indispensable.
The resulting dataset is a balanced panel of 799 units observed for \( T = 6 \) periods, for a total of 3995 observations.

The models estimated in Stewart (2006) are a pooled probit, a RE probit (with no special treatment for the initial conditions), the DP and the ADP. The first two columns of Table 4 show the estimation results of the pooled probit and of the the RE probit. In the first case, the estimates of both the coefficients and standard errors are identical to those obtained by Stewart (2006), whereas the estimates of the RE probit (with 24 quadrature points) exhibit very small differences (the coefficient associated with \( \text{union}_{t-1} \) is 1.1507 in Stewart (2006) compared to 1.1509, and so on).

The third column of Table 4 reports the estimation results of the DP model, using 24 quadrature points. In this case, estimated coefficients, standard errors and the value of the log-likelihood at convergence are identical.\(^7\) The fourth and fifth columns of Table 4 show the estimation results of the DP model using GHK instead of GHQ and of the ADP, both using 500 Halton points. While substantially similar, the results do present some discrepancies from those obtained by Stewart (2006). Such differences can probably be ascribed to the use of Halton sequences in DPB as opposed to random draws from the uniform distribution in the command written by Stewart (2006). Nevertheless, both sets of estimates show that ignoring the autocorrelation in the unobservables leads to the underestimation of the state dependence effect in these data. Finally, Table 5 reports the estimation results for the GADP and the QE model. In the first case, the results are very similar results to those obtained by estimating the ADP model, which is expected since the additional correlation coefficient \( \tau \) is positive and close to unity. In the second, the values of the estimated coefficients are coherent with those of the RE models with no autocorrelation.

Since DPB handles unbalanced datasets, we repeat the exercise keeping all the usable observations. Starting from the full dataset at our disposal (\texttt{union.full.gdtb}), the \texttt{DPB_setup} function for RE models automatically sub-samples the dataset as described in Section 3: out of the 4434 units 3790 are kept, while 400 are dropped because observed only once and 244 because are never observed for at least two consecutive periods. Table 6 reports the estimation results based on this dataset and only for the models implemented in DPB. Retaining all usable units in the dataset considerably increases the estimate of the state dependence parameter in all models while reduces the estimated persistence due to time invariant unobserved heterogeneity.

### 5.2 Example 2

In the following, we show how to implement in Gretl the popular RE estimator for dynamic binary models proposed by Wooldridge (2005), CDP (Conditional DP) henceforth. To this aim, we use the same dataset available in the data archive of the Journal of Applied Econometrics, also available in Gretl data archive. The data are a balanced panel of workers, extracted from the U.S Longitudinal Survey of Youth, which comprises 545 observed for \( T = 7 \) periods, from 1981 to 1987.

The method proposed by Wooldridge (2005) relies on specifying a distribution for the individual unobserved heterogeneity conditional on the initial value of the dependent variable and the observed history of strictly exogenous explanatory variables. Following the paper, to which we refer the reader to for details, the distribution of the individual unobserved effect is specified as

\[^7\]The reader should keep in mind that we directly estimate \( \sigma_\alpha^2 \) while Stewart (2006) estimates \( \lambda = \frac{\sigma_\alpha^2}{\sigma_\epsilon^2} \).

Standard errors (in parentheses) are computed using the Hessian. Number of quadrature points: 24; Number of GHK Halton draws: 500.

\[
\alpha_i | y_{i1}, w_i \sim N(\delta_0 + \delta_1 y_{i1} + \delta_2 w_i; \sigma^2)
\]

where \(y_{i1}\) is the initial observation and \(w_i\) contains the whole sequence of the strictly exogenous covariate \(w_{it}\) as in the approach of Chamberlain (1980). Notice that we use a different notation of the variance parameter as we will use \(\sigma^2\) to denote the variance of the unconditional distribution.

### 5.2.1 Estimation of the CDP probit

As is well known, the main virtue of the CDP model is that it can be easily estimated by means of standard routines used for the static RE probit with additional regressors. In Section 6 of Wooldridge (2005) the CDP model is estimated with \(\text{union}_{it}\) as the dependent variable, a dummy variable \(\text{married}_{it}\) and time dummies as explanatory variables. In addition, the whole history of \(\text{married}\) and the initial observation \(\text{union}_{i80}\) are included in the set of regressors to account for the conditional distribution of \(\alpha_i\). A second specification is also used, where the set of regressors contains also \(\text{edu}\) (years of schooling) and the dummy \(\text{black}\). The practice of including lags and leads of a time-varying strictly exogenous variable is often adopted by practitioners as a preventive measure against possible correlation between the random effect and the covariates. For this reason, a static/dynamic model with this feature is often referred to as a CRE (Correlated Random Effects) approach.

The hansl script to replicate the results in Table I, p. 52 of Wooldridge (2005) is
Table 5: Estimation results: GADP and QE models

Standard errors (in parentheses) are computed using the Hessian. Number of GHK Halton draws: 500. For the last column, the coefficients related to the second block of covariates refers to the parameters for the last observation in (7).

```
list TIME = dummify(year)
TIME -= Dyear_2
list MARR = marr8*
list X = const union_1 union80 married MARR TIME
probit union X --random-effects --quadpoints=12
probit union X educ black --random-effects --quadpoints=12
```

where, after creating the list of explanatory variables, the two `probit` commands with the `--random-effects` flag estimate the CDP models. The default number of quadrature points has to be set to 12 to have an exact replication of Wooldridge’s original results.

For comparison purposes, we use the same specifications to estimate the DP model with the CRE approach. The code, also containing the above script, is given in the file `union_example21.inp` and the estimation results are displayed in Table 7. The results in the first two columns of the table perfectly replicate the results in Wooldridge (2005). In addition, the same models estimated as DP models produce very similar results, as to be expected from the simulation study in Akay (2012).

The Mundlak version (Mundlak, 1978) of the CRE approach is also very popular among practitioners: instead of lags and leads, the regression is augmented by the within group mean of one or more time-varying strictly exogenous covariate. This estimator can easily

Standard errors (in parentheses) are computed using the Hessian. Number of quadrature points: 24; Number of GHK Halton draws: 500.

be implemented in Gretl by means of dedicated panel-data functions, available to the user after setting the panel data structure. In the script file `union_example21.inp`, the within group mean of the variable `married` is readily created in the line `m_marr = pmean(married)`. Using the baseline specification in Wooldridge (2005), we estimate the CDP and DP models with the Mundlak’s CRE specification. The results are displayed in Table 8.

5.2.2 Computation of Partial Effects

One of the reasons why RE models are often preferred to FE models by practitioners is the possibility of computing Partial Effects (PE), that have a meaningful economic interpretation in terms of probability variations. While the computation of PE is straightforward in models for cross-sectional data, additional sources of complication arise when dealing with panel data, mainly because the individual unobserved effect $\alpha_i$ enters the index function. However, in CRE models, the unobserved heterogeneity is represented by the estimated conditional mean of $\alpha_i$, that enters the predicted probability additively to the index function. In the following we show how to compute predicted probabilities by Hansl scripting, that can be used to derive PE or Average PE (APE).

As an example, Wooldridge (2005) computes the estimated probability of being in a union in 1987 conditional on being or not in a union in 1986 and on being married or not. After estimating the RE model and saving the relevant quantities, the predicted probabilities can easily be computed by means of a few lines of code. For instance, the probability of being in a union in 1987, conditional on being in a union in 1986 and being married,
\[ \Pr(\text{union}_{1987} = 1 \mid \text{union}_{1986} = 1, \text{married}_i = 1, x_{it}, w_i), \] can written as

\[ \Phi \left( \hat{\gamma} + \hat{\delta}_0 + \hat{\delta}_1 \text{union}_{1980} + \hat{\beta} + w'_i \hat{\delta}_2 + \hat{\beta}_{1987} \right) \]

and is computed as

\begin{verbatim}
list X = const union_1 union80 married MARR TIME
probit union X --random-effects --quadpoints=12 --quiet
k = nelem(X)
bw = $coeff[1:k]
s2a = exp($coeff[k+1])
series ndx /= sqrt(1+s2a)
wp11_m = cnorm(ndx)
\end{verbatim}

After the model estimation command is invoked on the second line, we retrieve the estimated parameters by means of the accessor $\text{coeff}$, which contains the parameter $\ln(s_\alpha)$ at the end. Then, we proceed to the computation of the index function, where $bw[1]$ is $\hat{\delta}_0$, $bw[2]$ is $\hat{\gamma}$, $bw[3]$ is $\hat{\delta}_1$, $bw[4]$ is the coefficient that multiplies the dummy $\text{married}$, $\text{lincomb}(\text{MARR}, bw[5:11])$ is $w'_i \hat{\delta}_2$ and $bw[17]$ is the coefficient for the 1987 time dummy. After the index function is normalised by $\sqrt{1+s_\alpha^2}$, the predicted probability is computed by the function \text{cnorm}, which returns the standard normal cdf. Similarly the estimated probabilities \( \Pr(\text{union}_{1987} = 1 \mid \text{union}_{1986} = 0, \text{married}_i = 1, x_{it}, w_i) \), and for $\text{married}_i = 0$, can be computed by appropriately excluding $bw[2]$ and $bw[4]$ from the index function calculation.

The top panel of Table 9 reports the average estimated probabilities in the four cases and is the equivalent of Table II on page 52 in Wooldridge (2005). APEs can readily be derived by taking cell differences: for instance, the state dependence for married individuals is 0.182, and so on. The lower panel of Table 9 reports the results for the same exercise performed on the estimated coefficients by the Heckman’s RE dynamic probit. In this case, the script file looks like

\begin{verbatim}
list X = const married MARR TIME
list Z = const married
b = DPB_setup(1,union,X,Z)
DPB_setoption(&b, "nrep", 12)
DPB_setoption(&b, "verbose", 0)
DPB_estimate(&b)
k = b.nk
z = b.nz
bh = b.coeff[1:k+1]
sig_a = b.coeff[k+z+3]
s2a = sig_a^2
series ndx /= sqrt(1+s2a)
series hp11_m = cnorm(ndx)
\end{verbatim}

This time, after estimating the model, estimated coefficients needs to be extracted form the bundle $b$, where they are stored into the vector $\text{coeff}$. The syntax $bh = b.coeff[1:k+1]$
and \( \text{sig}_a = \text{b.coeff}[k+z+3] \) extracts the needed estimates according to the order in which they are stored. The index function and the estimated probabilities are computed as in the previous exercise.

The script file \textit{union-example22.inp} contains the code to replicate the full Table 9. An alternative way to compute estimated probabilities would be to use the Gauss-Hermite quadrature to integrate \( \alpha_i \) out of the standard normal cdf. For brevity we do not illustrate this procedure here, however we do provide the script file \textit{union-example22-quad.inp} that computes the same average estimated probabilities by numerical integration.

\section{Conclusions}

The aim of the \texttt{DPB} function package is to provide the practitioner with an intuitive and simple-to-use tool for the estimation of panel data dynamic binary choice models, whose adoption is often called for in applied microeconometrics. Hopefully, \texttt{DPB} will allow practitioners, who may otherwise be discouraged by the complexity that arises from implementing these estimators in-house, to easily employ these estimators in standard research problems.

\section{Acknowledgements}

We are immensely grateful to Matteo Picchio, for thoroughly testing the function package and for his many comments on the manuscript, and to Allin Cottrell for providing assistance with the \texttt{Gretl} supporting infrastructure.
